

- Track described by **5-parameter state vector** at each point along its path
- **State vector** propagated step-by-step toward target
  - **Multiple scattering** and **energy loss** taken care of at each step
  - Does not require inversions of large matrices (at most 2x2 for FDC hits)
  - Jacobian matrix elements computed analytically
- State vector treated as a perturbation to an initial guess
  - Generate **reference trajectory** by swimming with initial parameters from the target
- Perform filter in three passes
  - Can iterate up to 10 times per pass, checking for  $\chi^2$  convergence
  - Regenerate reference trajectory based on results of previous pass

# Algorithm

Start with seeds coming from CDC and FDC track finding code (helical fits)

# Forward Tracking

- State vector  $\{x, y, t_x = dp_x / dp_z, t_y = dp_y / dp_z, q/p\}$ 
  - “Fitted” state vector considered as small perturbation relative to a **seed**
    - **Seed** determined from list of **track candidates** using helical model
- First step: create reference trajectory from seed, swimming from “vertex” to most downstream FDC hit
  - Take into account multiple scattering and energy loss when stepping through the field – *only do this for the reference trajectory...*
- Measurements added one by one, starting with most downstream hit
  - Apply Lorentz corrections at this stage
  - Iterate up to 10 times – generally only 2 or 3 iterations needed for convergence
  - CDC hits included without changing state vector

# Central Tracking

- Start out by swimming a reference trajectory as for forward tracking

- Use central parameters:

$$\{q/p_T, \phi, \tan \lambda, D, z\}$$

- $D$ =distance of closest approach to the reference trajectory at a given time along the particle's path
  - Origin of coordinate system for  $D$  moves from point to point along reference trajectory

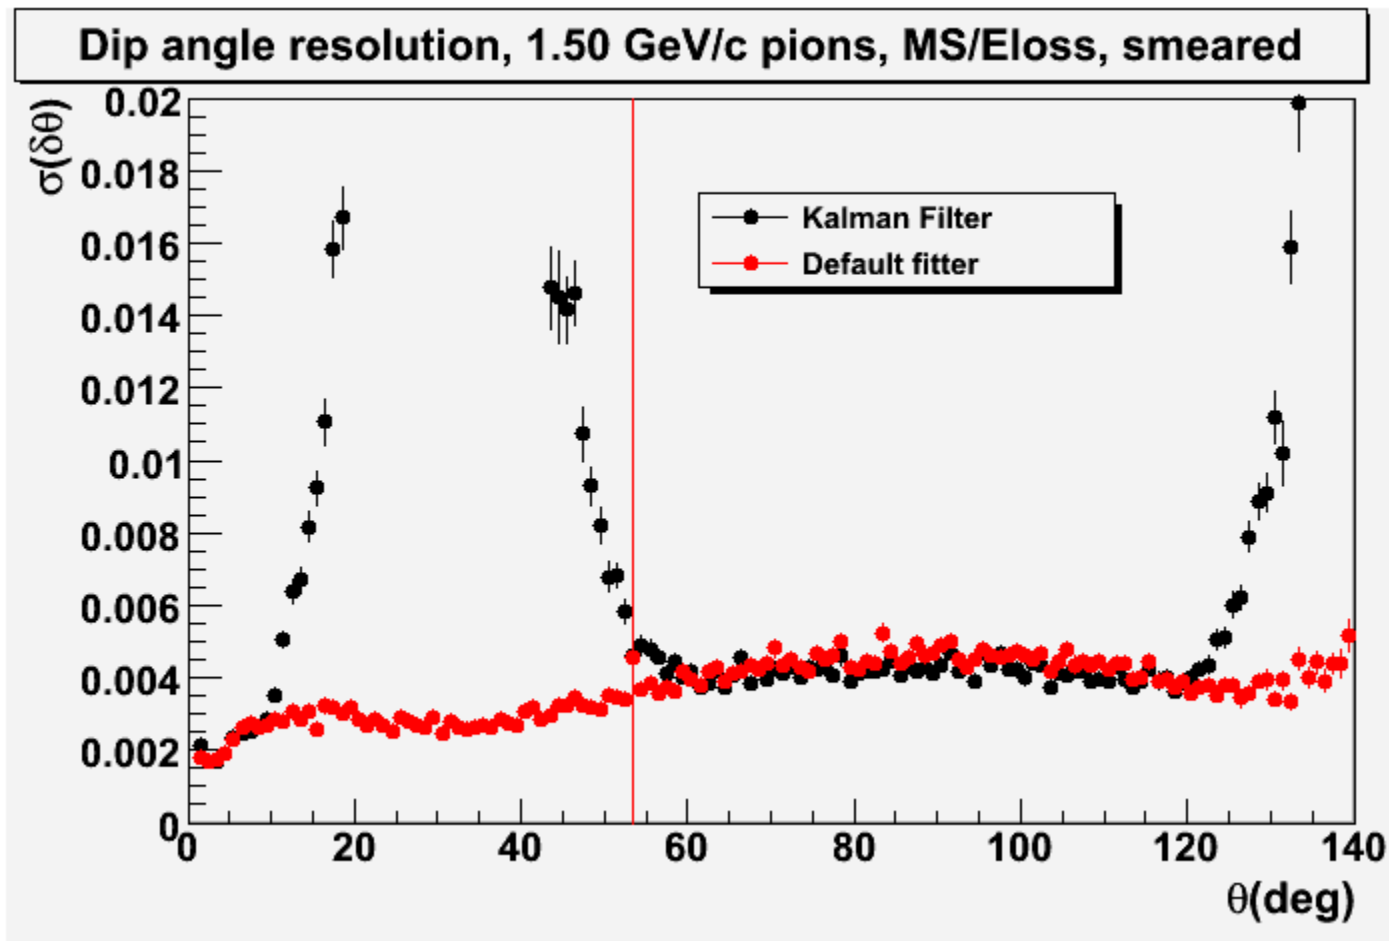

- Initial guess for covariance matrix (off-diagonal elements=0)

$$(\Delta p_T/p_T) = 10\%, \quad \sigma_D = 1 \text{ mm}, \quad \sigma_z = 3 \text{ mm}, \quad \sigma_\phi = 10 \text{ mrad}, \quad \sigma_\lambda = 10 \text{ mrad}$$

# Transverse Momentum Resolution

# Dip Angle resolution

# Azimuthal angle resolution

# Momentum magnitude resolution

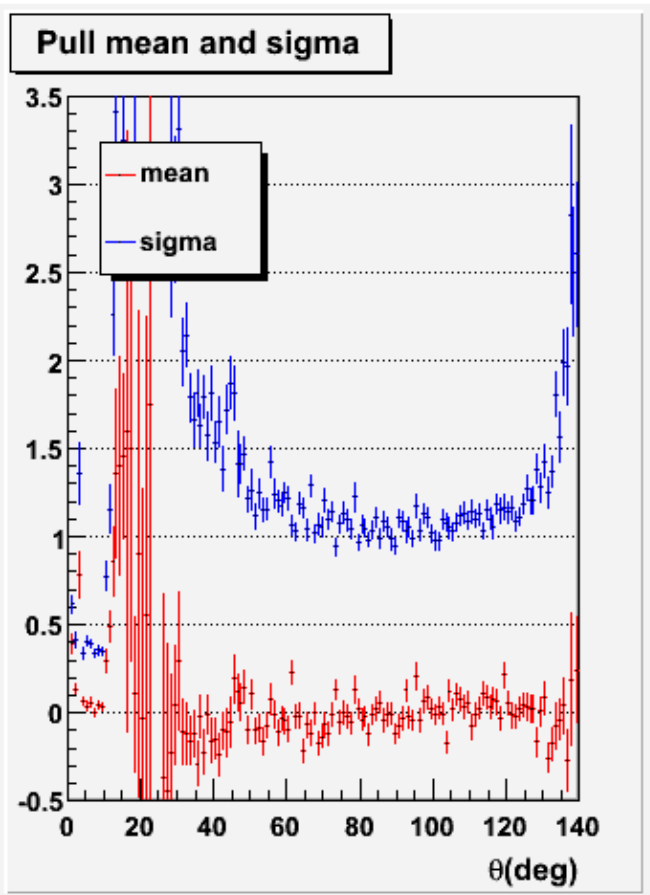

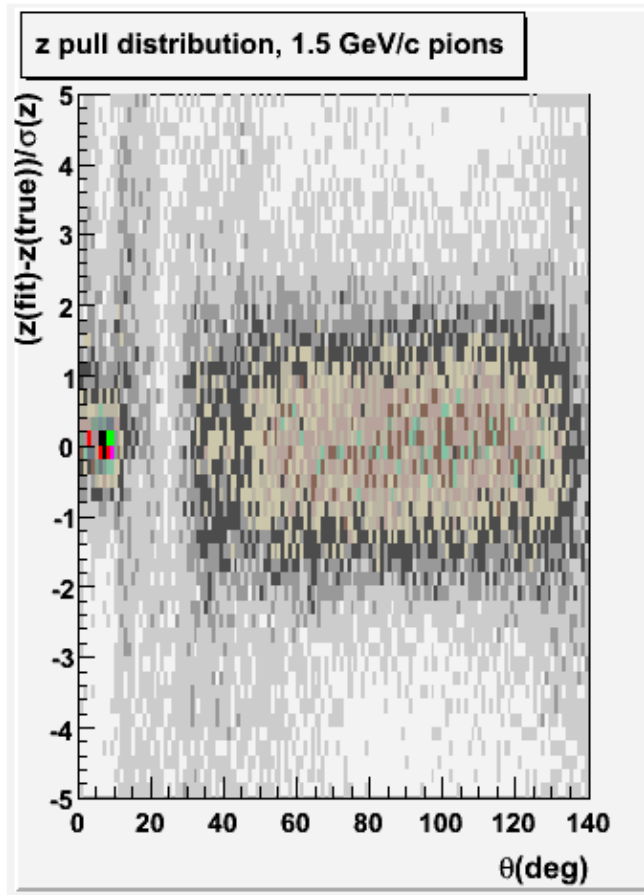

# Pull Distributions

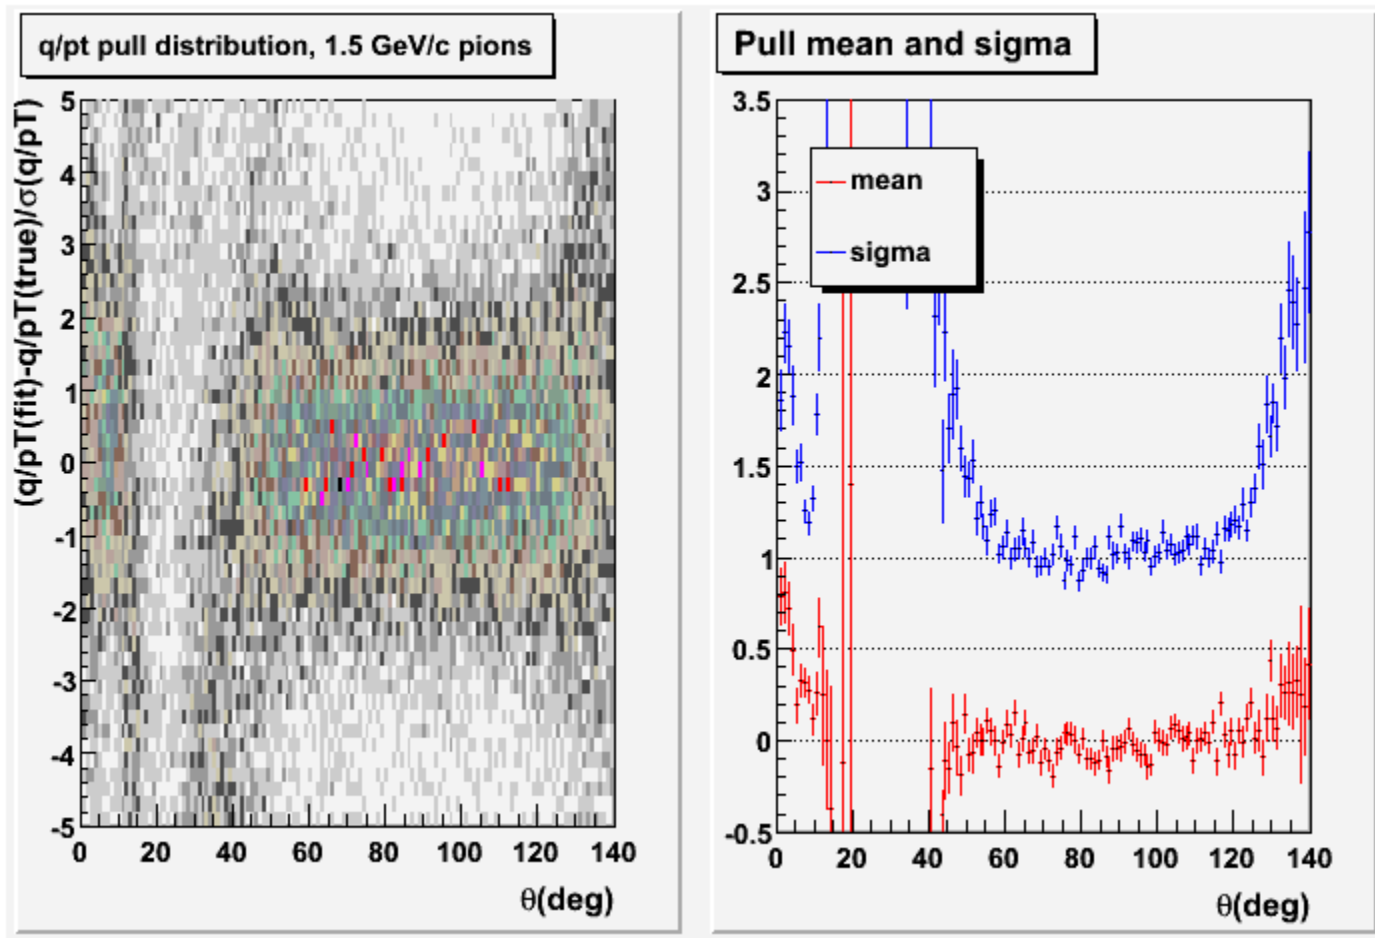

- Check for biases, check that errors are correct

$$Pull(z) = \frac{z - z_{true}}{\sqrt{\sigma^2(z)}}$$

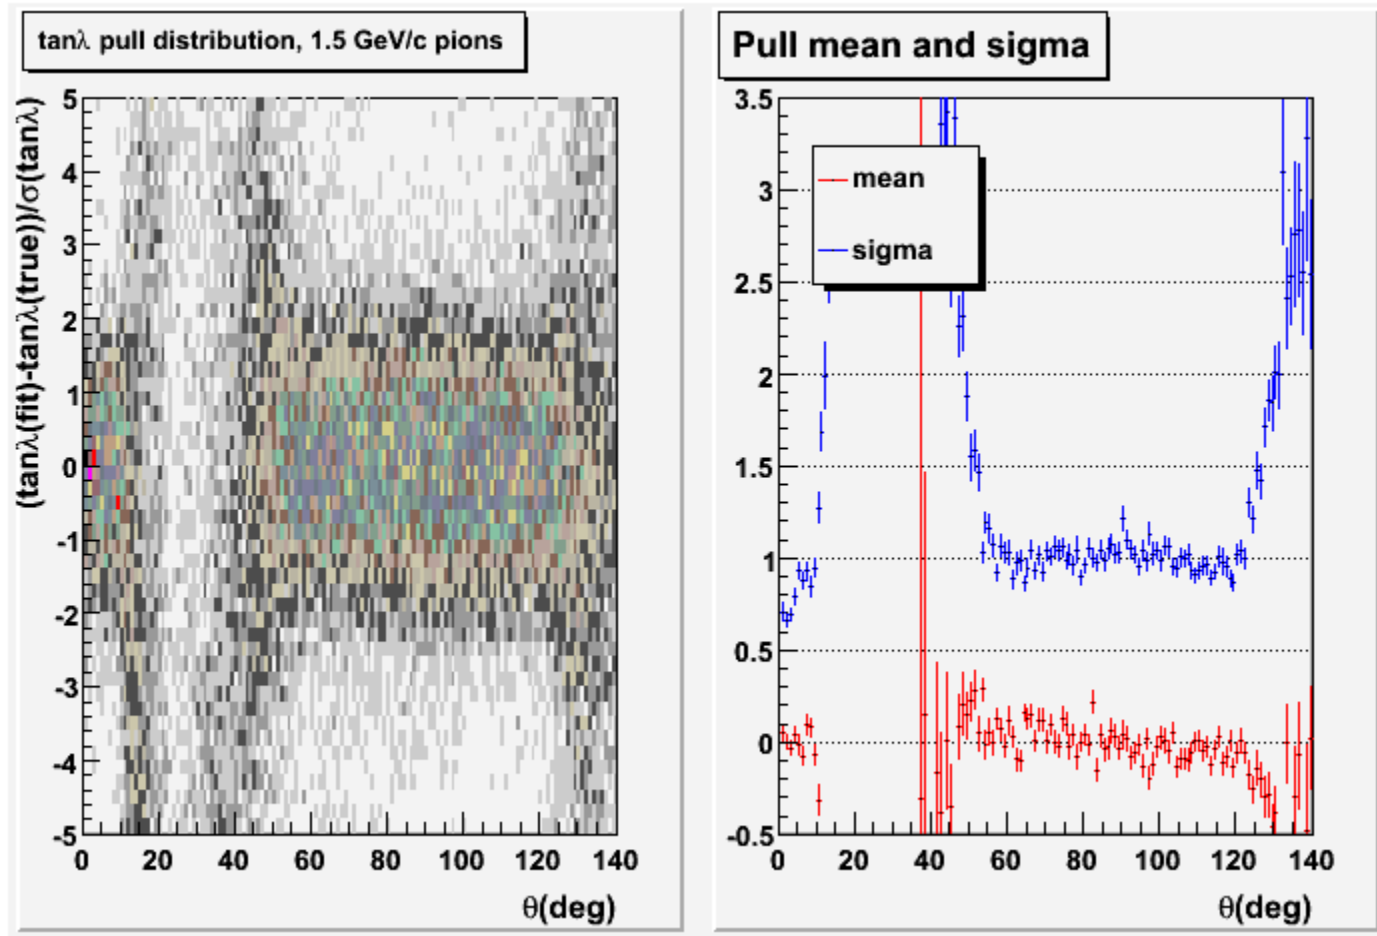

- Mean should be 0
- Standard deviation should be 1

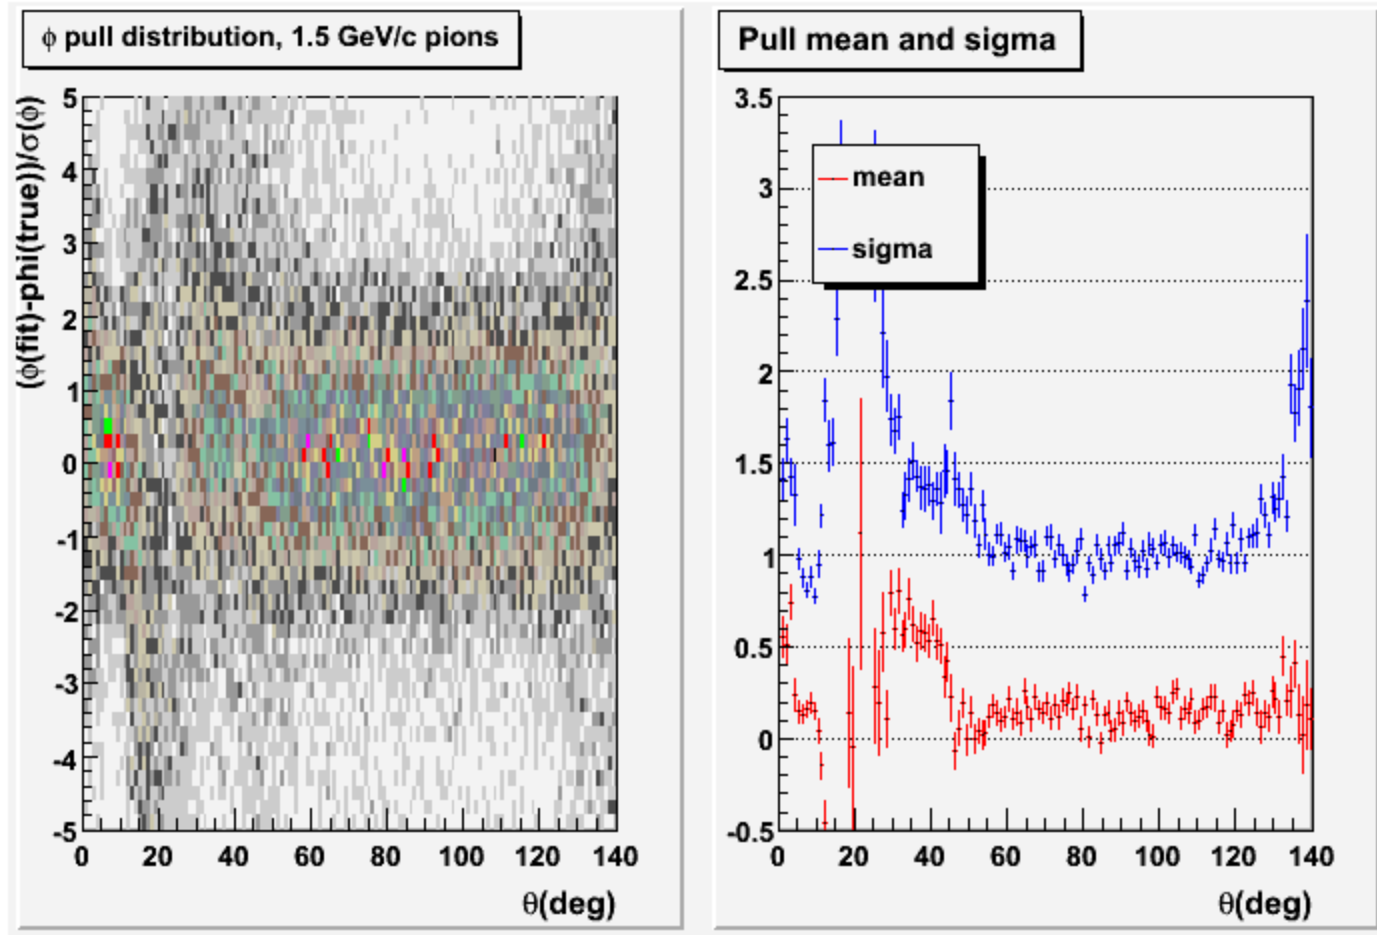

# Pull Distribution for $q/p_T$

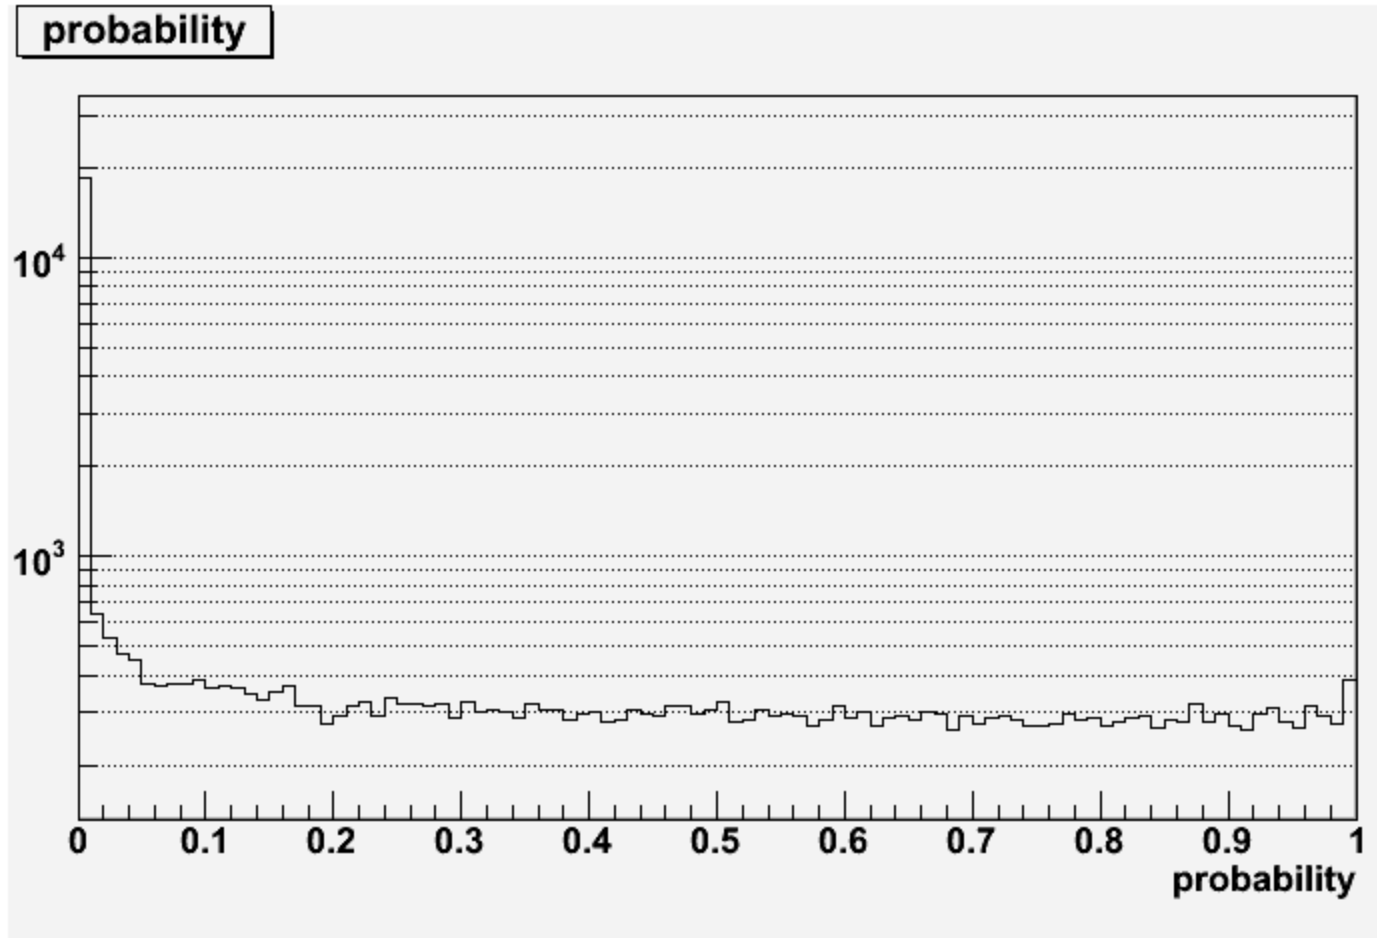

# Pull Distribution for $\tan\lambda$

# Pull Distribution for $\phi$

# Probability distribution

# Summary/Outlook

- Kalman filter now working well for  $60^\circ < \theta < 120^\circ$ 
  - Pull distributions have mean  $\sim 0$ ,  $\sigma \sim 1$
  - Probability distribution is flat
- Code is failing for  $\theta > 120^\circ$  and  $10^\circ < \theta < 60^\circ$ 
  - Still investigating source of discrepancy between Kalman filter and least squares fitter
  - Suspect issues with dealing with material (multiple scattering)
    - Do we need to include variations in position as well as angles?
